Abstract. In this paper, we present an adaptation of the sequence-to-sequence model for structured output prediction in vision tasks. In this model the output variables for a given input are predicted sequentially using neural networks. The prediction for each output variable depends not only on the input but also on the previously predicted output variables. The model is applied to spatial localization tasks and uses convolutional neural networks (CNNs) for processing input images and a multi-scale deconvolutional architecture for making spatial predictions at each time step. We explore the impact of weight sharing with a recurrent connection matrix between consecutive predictions, and compare it to a formulation where these weights are not tied. Untied weights are particularly suited for problems with a fixed sized structure, where different classes of output are predicted in different steps. We show that chained predictions achieve top performing results on human pose estimation from single images and videos.

Keywords: CNN, structured prediction, RNN, human pose estimation

Introduction

Structured prediction methods have long been used for various vision tasks such

Structured prediction methods have long been used for various vision tasks such as segmentation, object detection and human pose estimation, to deal with complicated constraints and relationships between the different output variables predicted from an input image. For example, in human pose estimation the location of one body part is constrained by the locations of most of the other body parts. Conditional Random Fields, Latent Structural Support Vector Machines and related methods are popular examples of structured output prediction models that model dependencies among output variables.

A major drawback of such models is the need to hand-design the structure of the model such that it captures important problem-specific dependencies amongst the different output variables and at the same time allows for tractable inference. For the sake of efficiency, a specific form of conditional independence amongst output variables is often assumed. For example, in human pose estimation, a predefined kinematic body model is often used to assume that each body part is independent of all the others except for the ones it is attached to.

To alleviate some of the above modeling simplifications, structured prediction problems have been solved with sequential decision making, where all earlier predictions influence later predictions. The SEARN algorithm [1] introduced a very general formulation for this approach, and demonstrated its application to various natural language processing tasks using losses from binary classifiers. A related model is the recently introduced sequence-to-sequence model, which has been applied to various sequence mapping tasks, such as machine translation, speech recognition and image caption generation [2,3,4]. In all these models the output is a sentence - where the words of the sentence are predicted in a first to last order. This model maximizes the log probability for output sequence conditioned on the input, by decomposing the probability of an output sequence with the multiplicative chain rule of probability; at each index of the output, the next prediction is made conditioned on all previous outputs and the input. A recurrent neural network is used at every step of the output and this allows parameter sharing across all the output steps.

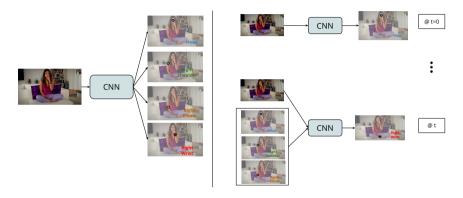

In this paper we borrow ideas from the above sequence-to-sequence model and propose to extend it to more general structured outputs encountered in computer vision – human pose estimation from a single image and video. The contributions of this work are as follows:

- A chain model for structured outputs, such as human pose estimation. The body part locations are predicted sequentially, where the prediction of each body part is dependent on all previously predicted body parts (See Fig. 1). The model is formulated using a neural network, in which the feature extraction and prediction models are learned end-to-end. Since we apply the model to spatial labelling tasks we use convolutional neural networks in both the inputs and outputs. The output convolutional neural networks is a multiscale deconvolution that we called deception because of its relationship to deconvolution and inception models [5,6,7]
- We demonstrate two formulations of the chain model one without weight sharing between different predictors (poses in images) and the other with weight sharing (poses in videos). The latter model is an RNN similar to the sequence-to-sequence model.

The above model achieves top performing results on the MPII human pose dataset – 86.2% PCKh. We achieve state-of-the art performance for pose estimation on the PennAction video dataset – 91.8% PCK.

## 2 Related Work

Structured output prediction as sequence prediction. The use of sequential models for structured predictions is not new. The SEARN algorithm [1] laid down a broad framework for such models in which a sequence of actions is generated by conditioning the next action on previous actions and the data. The optimization method proposed in SEARN is based on iterative improvement over policies using reinforcement learning. The model has been applied to various NLP tasks and even toy object detection problems.

**Fig. 1.** A description of our model for the task of body pose estimation compared to pure feed forward nets. **Left**: Feed forward networks make independent predictions for all body parts simultaneously and fail to capture contextual cues for accurate predictions. **Right**: Body parts are predicted sequentially, given an image and all previously predicted parts. Here we show the chain model for the prediction of *Right Wrist*, where predictions of all other joints in the sequence are used along with the image.

A similar class of models are the more recent sequence-to-sequence models [2,8] that map an input sequence to an output sequence of fixed vocabulary. The models produce output variables, one at a time, conditioned on inputs and previous output variables. A next-step loss function is computed at each step, using a recurrent neural network. Sequence-to-sequence models have been shown to be very effective at a variety of language tasks including machine translation [2], speech recognition [3], image captioning [4] and parsing [9]. In this paper we use the same idea of chaining predictions for structured prediction on two vision problems - human pose estimation in individual frames and in video sequences. However, as exemplified in the pose estimation case, since we have a fixed output structure we are not limited to using recurrent models.

In the pose prediction problem, we used a fixed ordering of joints, that is motivated by the kinematics of the human body. Prior work in sequential modelling has explored the idea of choosing the best ordering for a task [10,11,12]. For example, Vinyals et al. [10] explored this question and found that for some problems, such as geometric problems, choosing an intuitive ordering of the outputs results in slightly better performance. However for simpler problems most orderings were able to perform equally well. For our problem, the number of joints being predicted is small, and tree based ordering of joints from head to torso to the extremities seems to be the intuitively correct ordering.

Human pose estimation Human pose estimation has been one of the major playgrounds for structured prediction models in computer vision. Historically, most of the research has focused on graphical models, starting with tree-based decompositions [13,14,15,16] motivated by kinematic models of the human body.

Many of these models assume conditional independence of a body part from all other parts except the parent part as defined by the kinematic body model (see pictorial structure model [13]). This simplification comes at a performance cost and has been addressed in various ways: mixture model of parts [17]; mixtures of full body models [18]; higher-order spatial relationships [19]; image dependent pictorial structures [20,21,22]. Like these above approaches, we assume an order among the body parts. However, this ordering is used only to decompose the joint probability of the output joints into a particular ordering of variables in the chain rule of probability, and not to make assumptions about the structure of the probability distribution. Because no simplifying assumptions are made about the joint distribution of the output variables it leads to a more expressive model, as exemplified in the experimental section. The model is only constrained by the ability of neural networks to model the conditional probability distributions that arise from the particular ordering of the variables chosen.

It is worth noting that there have been models for pose estimation where parts are sequentially refined [23,24,25]. In these models an initial prediction is made of all the parts; in subsequent steps, all part predictions are refined based on the image and earlier part predictions. However, note that the predictions for models are initially independent of each other.

### 3 Chain Models for Structured Tasks

Chain models exploit the structure of the tasks they are designed to tackle by sequentially predicting their outputs. To capture this structure each output prediction is conditioned on all outputs predicted already. This philosophy has been exploited in language processing where sentences, expressed as word sequences, need to be predicted [2,8] from inputs. In recent automatic image captioning work [4,26], for example, a sentence Y is generated from an image X by maximizing the likelihood  $P(Y \mid X)$ . The chain rule is applied, consecutively to model each output  $Y_t$  (here a word) given the image X and all the previous outputs  $Y_{< t}$  in the output sequence.

In computer vision, recognition problems, such as segmentation, detection and pose estimation, demonstrate rich structure with complex dependencies. In this work, we model this structure with a simple and efficient recognition machine that makes little to no assumptions about the structure, other than the ability of a neural network to model complex, incremental conditional distributions.

Mathematically, let  $Y = \{Y_t\}_{t=0}^{T-1}$  be the T objects to be detected. For example, for the pose prediction problem,  $Y_t$  is the location of the t-th body part. In video prediction problems,  $Y_t$  is the location of an object in the t-th frame of a video. Using the chain rule we decompose  $P(Y = y \mid X)$  as follows:

$$P(Y = y \mid X) = P(Y_0 = y_0 \mid X) \prod_{t=1}^{T-1} P(Y_t = y_t \mid X, y_0, ..., y_{t-1})$$
(1)

From the above equation, we see that the likelihood of assigning value  $y_t$  to the t-th variable is given by  $P(Y_t = y_t | X, y_0, ..., y_{t-1})$ , and depends on both

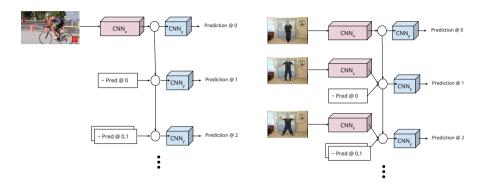

Fig. 2. A visualization of our chain model. Left: single image case. Right: video case. In both cases, an image is encoded with a CNN (CNN<sub>x</sub>). At each step, the previous output variables are combined with the hidden state, through the sequential modules. A CNN decoder (CNN<sub>y</sub>) makes predictions each step, t. There are two differences between the two cases: (i) for video CNN<sub>x</sub> receives at each step a frame as an input, while for single image there is no such input; (ii) for video CNN<sub>y</sub> share parameters across steps, while for single image the parameters are untied.

the input X as well as the assignment of previous variables. In this work, we model the likelihood  $P(Y_t = y_t | X, y_0, ..., y_{t-1})$  with a convolutional neural network (CNN). The direct dependence of the current prediction on the ground truth values of previous variables allows for the model to capture all necessary relationships without making any assumption about the joint distributions of all the variables, other than assuming that each successive conditional distribution,  $P(Y_t = y_t | X, y_0, ..., y_{t-1})$ , can be computed with a neural network.

# 3.1 Chain Models for Single Images

In the case of single images, the input X is the image while the t-th variable  $Y_t$  can be, for example, the location of the t-th object in image X (see Fig. 2).

The probability of each step in the decomposition of Eq. (1) is defined through a hidden state  $h_t$  at step t, which carries information about the input as well as states at previous steps. In addition it incorporates the values  $y_{< t}$  from previous steps. The final probability for variable  $Y_t$  is computed from the hidden state:

$$h_t = \sigma(w_t^h * h_{t-1} + \sum_{i=0}^{t-1} w_{i,t}^y * e(y_i))$$
 (2)

$$P(Y_t = y_t \mid X, y_0, ..., y_{t-1}) = \text{Softmax}(m_t(h_t))$$
(3)

In the above equation, the previous variables are first transformed through a full neural net  $e(\cdot)$ . Parameters  $w_t^h$  and  $w_{i,t}^y$  then linearly transform the previous hidden state and a function of previous output variables,  $e(\cdot)$ , and a non-linearity  $\sigma$  is then applied to each dimension of this output. The nonlinearity  $\sigma$  of choice

is a Rectified Linear Unit. Finally, \* denotes multiplication. In image applications, however, the hidden state h can be a feature map and the prediction y a location in the image. In such cases, \* denotes convolution and e is a CNN. Note that, as long as we feed in just the last variable  $y_{t-1}$  in this equation, the recurrent equation insures that we condition on the entire history of joints. However feeding in more of the previous joints makes it easier for the model to learn the conditional distributions directly. In the computation of the conditional probability of  $y_t$  from  $h_t$  we use another neural net  $m_t$ , which produces scores for potential object location. By applying a softmax function over these scores we convert them to a probability distribution over locations.

The initial state  $h_0$  is computed based solely on the input X:  $h_0 = \text{CNN}(X)$ . The above formulation is reminiscent of recurrent networks (RNNs) – the equations define how to transform a state from one step to the next. We differ, however, from RNNs in one important aspect – the parameters in Eq. (2-3) are not necessarily tied; indeed, parameters  $w_t^h$  and  $w_{i,t}^y$  are indexed by the step. This design choice is appropriate for tasks such as human pose estimation where the number of outputs T is fixed and where each step is different from the previous steps. In other applications, such as video, we tie these parameters:  $w_i^h = w_0^h$  and  $w_{u,t}^y = w_{i,1}^y$  for all i and t.

### 3.2 Chain Models for Videos

For videos, the input is a sequence of images  $X = \{X_t\}_{t=0}^{T-1}$  (see Fig. 2(b)). Here predictions are made at each step, as the images are fed in. At each step t we want to make predictions for the image  $X_t$  at that step, using the past images, and the past output variables. Thus, we propose to modify the equation for the hidden state as follows:

$$h_t = \sigma(w_t^h * h_{t-1} + \text{CNN}(X_t) + \sum_{i=0}^{t-1} w_{i,t}^y * e(y_i))$$
(4)

where we add features extracted from image  $X_t$  using a CNN. The final probability is computed as in Eq. (3).

In videos we often need to predict the same type of information at each step, e.g. location of all body joints of the person in the current frame. As such, the predictors can have the same weights. Thus, we tie the parameters  $w_t^h$ ,  $w_{i,t}^y$ , and  $m_t$  together, which results in a convolutional RNN.

As before, the connections from hidden state at the previous step, guarantees that the prediction at each time step uses output variables from all previous steps, as long as the previous output variable  $Y_{t-1}$  is fed in at time t. However, feeding in a larger time horizon  $T_H$ , leads to an easier learning problem.

# 3.3 Improved Learning with Scheduled Sampling

So far, we have described the method as using the input, and only ground truth values of the previous output variables when making a prediction for the next

output variable. However, it has previously been observed that for sequence-to-sequence models, overfitting can be mitigated by probabilistically substituting ground truth values of previous output variables, with samples from the probability distribution predicted by the model [27]. One challenge that arises in this is that, at the start of the training, the predicted probability distributions are wildly inaccurate, and thus feeding in samples from the distribution is counterproductive. Thus, the authors of that paper proposed a method, called *scheduled sampling*, that uses an annealing schedule that feeds in only the ground truth outputs at the start of the training and increases the rate of sampling from the predictions of the model towards the end of the training. We used scheduled sampling in our paper and found that it lead to improved results.

# 4 Experimental Evaluation

To evaluate the proposed model, we apply it on human pose estimation, which is challenging and of great interest due to the complex relationship among body parts. In the single image case, we use the chain model to capture the structure of pose in space, i.e. how the location of a part influences others. For the videos, our model captures the constraints and dynamics of the body pose in time.

Tasks and Datasets For our single image experiments we use the MPII Human Pose dataset [28], which consists of about 40K instances (28K for train and 12K for validation) of people performing various actions. All frames (apart for the test set) come with a maximum of 16 annotated joints (*Top Head, Neck, Right Ankle, Left Knee*, etc.). For the task of pose estimation in video we use the Penn Action dataset [29], which consists of 2326 video sequences (split in half for train and test) of people performing various sports. All frames come with a maximum of 13 annotated joints. During evaluation, if a joint prediction lies within a predefined distance from the ground truth location it is counted as a correct detection. The predefined distance is proportional to the size of the person in question, which is estimated through the person's head size or total height. This metric is called PCK, and is further described in [30,28].

The model we use is defined in Fig. 2. We experiment with two different choices for  $\mathrm{CNN}_x$ , the network which encodes the input image. First, a shallow convolutional neural network which consists of 6 layers each followed by a rectified linear unit [31] and Batch Normalization [32]. The first 4 layers include max pooling with stride 2, thus leading to an effective stride of 16. This network is described in Fig. 3. Second, we experiment with a deeper network of identical architecture to inception-v3 [33]. We throw away the last convolutional layer of inception-v3 and connect the output to  $\mathrm{CNN}_y$ .

The  $\mathrm{CNN}_y$  network decodes the hidden state to a heatmap over possible locations of a single body part. This heatmap is converted to a probability distribution over locations using a softmax. The network consists of 2 towers of deconvolutional layers each of which increases the width and height of the feature maps by a factor of 2. Note the that the deconvolutional towers are multi-scale -

in one layer, different filter sizes are used and combined together. This is similar to the inception model [5], with the difference that here it is applied with the deconvolution operation, and, thus, we call it *decention*.

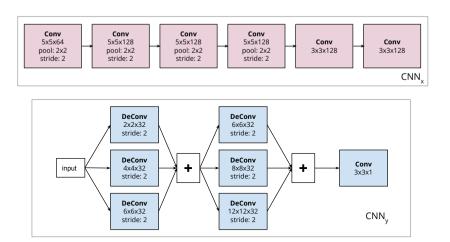

Fig. 3. Description of the components of our network,  $\text{CNN}_x$  and  $\text{CNN}_y$ . Each box represents a convolutional or deconvolutional layer, where  $w \times h \times f$  denotes the width w, the height h of the filters and f denotes the number of filters. In each layer the filter is applied with stride 1 if not noted otherwise. Finally, in each layer after the filtering operation a ReLU and batch normalization are applied.

# 4.1 Pose Estimation From a Single Image

In this application case we use the chain model to predict the joints sequentially. The sequence with which the joints are processed is fixed, and is motivated by the marginal distributions of the joints. In particular, we sort the joints in descending order according to the detection rates of an unchained feed forward net. This allows for the easy cases to be processed first (e.g. Torso, Head) while the harder cases (e.g. Wrist, Ankle) are processed last, and thus use the contextual information from the joints predicted before them.

**Inference** At test time, we use beam search to infer the optimal location of the joints. Note that exact inference is infeasible, due to the size of the search space (a total of  $(HW)^T$  possible solutions, where  $H \times W$  is the size of the prediction heatmap and T are the number of joints). At each step t, the best B predictions are kept, where each prediction is the sequence of the first t joints. The quality of a full body pose prediction is measured by its log-probability, which is the sum of the log-probabilities corresponding to the individual joint predictions.

An exact implementation of chain rule conditions on predictions made at every step. Alternatively, one could skip the non-differentiable sampling operation and use the probability distribution from all previous tasks directly. Even though this is not an exact application of the chain rule, it allows for the gradients to flow back to the output of each task. We found that this approximation of the chain rule led to very similar results in terms of performance, however it slowed down training time by a factor of 3. On the other hand, inference became faster by a factor of B.

**Learning details** We use an SGD solver with momentum to learn the model parameters by optimizing the loss. The loss for one image X is defined as the sum of losses for individual joints. The loss for the k-th joint is a the cross entropy between the predicted probability  $P_k$  over locations of the joint and the ground-truth probability  $P_{\rm gt}$ . The former is defined based on the heatmap  $h_k$  output by CNN $_y$  for the k-th joint:  $P_k(x,y) = \frac{e^{h_k(x,y)}}{\sum_{(x',y')} e^{h_k(x',y')}}$ . The latter is defined based on a distance r – all locations within radius r of the ground-truth joint location are assigned same nonzero probability  $P_{\rm gt}(x,y) = 1/N$ , all other locations are assigned probability 0. N is a normalizer guaranteeing  $P_{\rm gt}$  is a probability.

The final loss for X reads as follows:

$$L(\{h_k\}_{k=1}^T) = \sum_{k=1}^T \sum_{(x,y)} P_{\text{gt}}(x,y) \log P_k(x,y)$$
 (5)

We use batch size of 16; initial learning rate of 0.003 that was decayed every 100K steps; radius of  $r = 0.01 \times (W+H)/2$ . The model was trained for 120K iterations. Our images are rescaled to 224 × 224. The weights of the network are initialized by sampling from a normal distribution of zero mean and 0.01 standard deviation.

**Results** Table 1 shows the PCKh performance on the MPII validation set of our chain model and our baseline variants.

Rows 1, 2 & 3 show the performance of pure feed forward networks for the task in question. The first row shows the performance of a 9 layer network, shallow  $\text{CNN}_x + \text{CNN}_y$ , which we call base network. The 3rd row is a similar network, where each deconvolutional tower, which we call deception, in  $\text{CNN}_y$  is replaced by a single deconvolution. The difference in performance shows that multi-scale deconvolutions lead to a better, very competitive baseline. Finally, the third row shows the performance of a very deep network consisting of 24 layers. This network has the same number of parameters and the same depth as our chain model and serves as the baseline which we improve upon using the chain model.

 $Row\ 4$  shows the performance of our chain model. This model improves significantly over all the baselines. The biggest gains are observed for Wrists and Ankles, which is a clear indication that conditioning on the predictions of previous joints provides cues for better localization.

 $Row\ 5$  shows the performance of our chain model with multi-crop evaluation, where at test time we average the predictions through flipping and jittering of the input image.

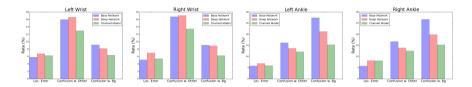

Row 6 shows the performance of an *oracle* chain model. For this model, at each step t we use the oracle (ground truth) locations of all previous joints. This model is an estimate of the upper bound performance of our chain model, as it predicts the location of a joint given perfect knowledge of the location of all other joints which precede it in the sequence.

Row 7 shows the performance of the inception base network  $CNN_x + CNN_y$ , where  $CNN_x$  is the inception-v3 [33]. We observe significant gains when using the inception-v3 architecture compared to a shallower 6 layer network for the encoder network, at the expense of more computations.

Row 8 shows the performance of the inception chain model. For both the inception base and chain model we use multi-crop evaluation. Also in both cases, the inception-v3 parameters were initialized with weights from an ImageNet model. The inception chain model leads to significant gains compared to its base network (row 7). The improvements are more evident for the joints of Wrist, Knee. Ankle.

Table 1. PCKh performance on the MPII validation set. Rows 1 and 2 show results for 9-layered CNN models, with multi-scale (deception) and single scale deconvolutions. Row three show results of a 24 layer model with deception, but without chained outputs. Row 4 shows results from our chain model with comparable depth and number of parameters as the 24 layer model, but with chained predictions. It shows clear improvement over the baselines. The performance is further improved using multiple crops of the input at test time, at row 5. Row 6 shows the error rate of the Oracle, where the correct values of previous output is fed into the network at each step. Row 7 and 8 show the performance of a base and chain model when inception-v3, pre trained on ImageNet, is used as the encoder network. Using a deeper architecture leads to substantially improved results across all joints.

PCKh (%)	Torso	Head	Shldr	Elbow	Wrist	Hip	Knee	Ankle	Mean
Base Network	86.8	91.9	85.8	74.5	69.0	71.1	61.4	50.6	73.9
Base Net. w/ single deconv.	86.0	91.7	85.1	72.9	68.0	69.4	59.7	48.5	72.6
Very Deep Base Network	88.1	92.0	86.1	74.1	67.7	73.7	64.7	58.0	75.6
Chain Model	86.8	93.2	88.3	79.4	74.6	77.8	71.4	65.2	79.6
Chain Model w/ multi-crop	88.7	94.4	90.0	82.6	78.6	80.2	74.8	68.4	82.2
Oracle Chain Model	87.2	95.9	93.4	83.3	82.3	95.2	77.6	72.3	85.9

Inception Chain Model	91.7	95.7	92.2	85.3	82.2	82.9	80.0	72.4	85.3

**Fig. 4.** Error analysis of the predictions made by the base network (blue), the very deep model (red) and our chain model (green), for *Wrist* and *Ankle*. Each figure shows the error rates, categorized in three classes, localization error, confusion with other joints and confusion with the background

Error Analysis In order to further understand the gains observed from the chain model, we perform an error analysis for the base network  $\text{CNN}_x + \text{CNN}_y$ , the very deep network and our chain model. For this analysis the encoder network  $\text{CNN}_x$  is the 6 layer CNN for all models. Similar to [34], we categorize the erroneous predictions into the three distinct categories: a) localization error, i.e. the prediction is within  $[\alpha, \beta] \times HeadSize$  of the true location, b) confusion with other joints, i.e. the prediction is within  $\alpha \times HeadSize$  of a different joint, and c) confusion with the background, i.e. the prediction lies somewhere else in the image. Note that in the PCKh metric, a prediction is correct if it falls within  $0.3 \times HeadSize$ . We set  $\beta = 0.5$ 

Figure 4 shows the error analysis for the hardest joints, namely Wrist and Ankle. Each plot consists of 3 sets of bars, the rates for error localization, confusion with other joints and confusion with background. It is clear from the plots that the chain model reduces the misses due to confusion with other joints and the background. For Wrists, the confusion with other joints seems to be the dominating error mode, and further analysis shows that the main source of confusion comes mainly from the opposite wrist and then the nearby joints. For Ankles, the biggest error mode comes from confusion with the background. This is because, ankles are usually heavily occluded and lack strong appearance cues.

Figure 5 shows some examples of our predictions on the MPII dataset.

Fig. 5. Examples of predictions made by our chain model on the MPII dataset

Comparison to Other Approaches We evaluate our approach on the MPII test set in order to compare to other methods on the task of pose estimation from a single image. Table 2 shows the results for our approach and other leading methods in the field. We show the performance of both versions of our chain model, with a shallow 6 layer encoder as well as the inception-v3 architecture. For the shallow chain model, we ensembled two chain models trained at different input scales. For the inception chain model, no ensembling was performed.

The leading approaches by Wei et al. [35] and Newell et al. [36] rely on iteratively refining predictions. In other words, predictions are made independently at first for all joints. These initial predictions are quite poor (see [35]), but are fed subsequently into a network for further refinement. On the other hand, our approach produces only one set of predictions via the chain model and does not refine them further. One could potentially combine the two ideas, the one of chained predictions and the one of iterative refinement, in order to achieve better results.

Table 2. Performance on the MPII test set. A comparison of our chain model, with a
shallow 6 layer and an inception-v3 encoder, with leading approaches in the field.

### 4.2 Pose Estimation From Videos

Our chain models in time are described in Equation 4 and shown in Figure 2. The task here is to localize body parts in time across video frames. The output variables from the joints of the previous frames are used as inputs to make a prediction for the joints in the current frame. We apply the chaining in two different ways - firstly only in time, where each joint is predicted independently of the other joints (as in our baseline models), but chaining is done in time, and secondly, with chaining both in time, and in joints.

**Pose Estimation in Time** As shown in the right hand side of Figure 2, the chain model sequentially processes the video frames. The predictions at the

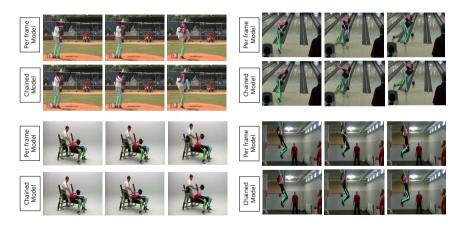

Fig. 6. Examples of predictions made by our chain model on the Penn Action dataset. The top row of each block shows the predictions made by the per frame model, while bottom row shows the detections of the chain model

previous time steps are used through a recurrent module in order to make a prediction at the current time step. Again, we use a heatmap to encode the location of a part in the frame.

The details of our learning procedure are identical to the ones described for the single image case. The only difference is that each training example is now a sequence of images  $X = \{X_t\}_{t=0}^{T-1}$  each of which has a ground-truth pose. Thus, the loss for X is the sum over the losses for each frame. Each frame loss is defined as in the case of single image (see Eq. (5)).

We train our model for 120K iterations using SGD with momentum of 0.9, a batch size of 6 and an initial learning rate of 0.003 with step decay 100K. We images are rescaled to  $256 \times 256$  and for the loss we use a relative radius of r = 0.03. The weights are initialized randomly from a normal distribution of zero mean and 0.01 standard deviation.

Table 3 shows the performance on the Penn Action test set. For consistency with previous works on the dataset [41], a prediction is considered correct if it lies within  $0.2 \times \max(s_h, s_w)$ , where  $s_h, s_w$  is the height and width, respectively, of the instance in question. We refer to this metric as PCK. (Note that this is a weaker criterion than the one used for the MPII dataset). We show the per frame performance, as produced by a base network  $\text{CNN}_x + \text{CNN}_y$  trained to predict the location of the joints at each frame. We also provide results after applying temporal smoothing to the predictions, via the Viterbi algorithm where the transition function is the Euclidean distance of the same joints in two neighboring frames. Additionally, we show the performance of an RNN, of a similar nature as our chain model. All networks have roughly the same numbers of parameters, for the sake of comparison. For our chain model in time, we show results for two choices of time horizon  $T_H$ . Namely,  $T_H = 1$ , where only predictions of the previous time step are being considered and  $T_H = 3$ , where predictions of the

past 3 frames are considered at each time step. Finally, we show the performance of a chain model in time and in joints, with a time horizon of  $T_H = 3$ .

Table 3. PCK performance on the Penn Action test set. We show the performance of our chain model for two choices of the time horizon  $T_H$  and compare against the perframe model, with and without temporal smoothing, and an RNN model. We also show the performance achieved by Nie et. al. [41]. Our chain model with  $T_H = 3$  improves the localization accuracy across all joints. (Note that the mean is derived from the average performance of all the joints, here shown under one semantic label for right and left sides)

PCK (%)	Head	Shldr	Elbow	Wrist	Hip	Knee	Ankle	Mean
Nie et. al. [41]	64.2	55.4	33.8	24.4	56.4	54.1	48.0	48.0
Base Network	94.1	90.3	84.2	83.5	88.7	87.2	87.7	87.5
Base Network	93.1	91.8	85.7	78.8	90.2	91.9	91.1	88.6
w/ smoothing	05.0	00.5	0= 0		01.1	20.0	00.1	00.1
RNN	95.3	92.5	87.9	87.5	91.1	89.8	90.1	90.1
Chain Model, $T_H = 1$	95.8	93.2	88.9	89.6	91.3	89.8	91.2	91.0
Chain Model, $T_H = 3$	95.8	94.1	90.0	90.2	91.3	90.6	91.8	91.7
Chain Model in time & joints, $T_H = 3$	95.6	93.8	90.4	90.7	91.8	90.8	91.5	91.8

We compare to previous work on the Penn Action dataset [41]. This model used action specific pose models and showed gains compared to Yang & Ramanan [30], however their performance is much lower, presumably because they used shallow hand-crafted features.

We observe a gain in performance compared to the baseline per frame CNN as well as the RNN across all joints. Interestingly, chain models improve arm prediction more than they improve on legs. This is due to the fact that people in the videos play sports which involve big arm movements, while the legs are mostly un-occluded and less kinematic. In addition, we see that  $T_H=3$  leads to better performance, which is not surprising since the model makes a decision about the location of the joints at the current time step based on observation from 3 past frames. We did not observe gains from using a larger time horizon. Lastly, chaining in time and in joints does not seem to improve performance even further. This might be due to the already high accuracy achieved by the time chain model.

Figure 6 shows examples of predictions from our chain model on the Penn Action dataset. We also show the predictions made by the per frame detector. We see that the chain model is able to disambiguate right-left confusions which occur often due to the constant motion of the person while performing actions, while the per frame detector switches very often between erroneous detections.

## 5 Conclusions

In this paper, motivated by sequence-to-sequence models, we have argued how chained predictions can lead to a powerful model for vision tasks involving structured prediction. Using chain models allows us to sidestep any assumptions about the joint distribution of the output variables, other than the capacity of a neural network to model conditional distributions. We have harnessed the expressive capabilities of deep convolutional neural networks to model the complicated conditional distributions. The application of this model to pose predictions on images and videos leads to top performing results on both tasks. Future work will attempt to incorporate visual attention models to refine predictions from the networks
